ABSTRACT

The minimum energy geometries and the electronic structure for noble metals clusters Agₙ, Auₙ, Ptₙ and Cuₙ, with number of atoms n varying from 3 to 10 atoms are obtained employing density functional theory (DFT) with generalized gradient approximation (GGA) performed in the SIESTA method. New lowest energy structures not reported previously are obtained. The lowest energy structures for (n ≤ 5) clusters are planar where the stability showed that the highest value in binding energy is present in platinum. The calculated second–order differences in energies, and the highest occupied orbital–lowest unoccupied orbital (HOMO–LUMO) energy gap, the density of state (DOS) shows peculiar odd–even oscillation behaviours, showing that Ag₄,6,8,10, Au₄,6,8,10, Cu₄,6,8,10 and Pt₃,7,9 clusters remain in highly stable in comparison with their neighboring clusters. (VIP) Vertical ionization potential is discussed then compared with other studies.

Keywords: Cluster, Noble metal, DFT, Electronic structure, Catalysts

INTRODUCTION

The study about of small clusters of group IB noble metals, e.g., gold, silver, copper and platinum have been previously intensively studied due to their large potential applicability originating from their unique optical, electronic, catalytic and magnetic properties, biological sensing and biomedicine [1,2]. Due to their shells (3d¹⁰4s¹ for copper, 4d¹⁰5s¹ for silver, 5d¹⁰4s¹ for gold and 6d¹⁰ for platinum), Cu, Ag, Au and Pt clusters lie between that of alkali metals and transition metals. The presence of d-type electrons strongly affects the physical and chemical properties of clusters. Due to the quantum size effects, discrete electronic levels are indeed observed in metal clusters smaller than 2 nm in diameter [3]. Moreover, the catalytic Characteristics of metallic particles are known, in certain circumstances, to be enhanced when the cluster is reduced [4-6].

The size dependent evolution of the structural and electronic properties of small noble metal clusters has been done the subject of many experimental and theoretical studies for many years. At the atomic level, the energetic position of the nd–levels is approximately 4 eV below the (n+1) s levels in silver, but only about 2 eV in copper, gold and platinum.

Recently, the most and stable structures of Agₙ, Auₙ, Cuₙ and Ptₙ clusters were determined n<10 calculated based on density functional theory (DFT) [7-14]. Our study successfully reproduced the result of stable geometries structures obtained in previous studies. Because considered in this work was subject to simulated annealing process.

COMPUTATIONAL DETAILS

The energy calculations in this work were based on the density functional theory (DFT) [15,16], within the generalized gradient approximation (GGA) [17], parameterized by Perdew, Burke and Ernzerhof (PBE) [18] using the plan-wave pseudo potential method. All the calculations were conducted with the SIESTA ab initio package [19,20], and the interaction between electron and ion were included by employing norm-conserving pseudo-potentials [21]. The pseudopotentials were created using the ATOM code [22] within the Troullier-Martins scheme [21].
A cubic super cell of 20 Å length was used in the calculation to ensure negligible interactions between image clusters. Due to the large cell used in the calculated, the Brillouin zone integration was approximated by a single point. The cut-off energy was set to 200 Ry. All the clusters Agn, Cun, Aun and Ptn considered in this work were subject to simulated annealing process. They were heated to temperatures around 1000 K in 1000 steps. Then, they were equilibrated at this temperature in 1000 steps, and very slowly cooled until 0 K in 500 steps. Finally, all the clusters were allowed to conduct a relaxation process at 0 K.

RESULTS AND DISCUSSION

Geometrical structures

The optimized geometric structures for gold, copper, silver, and platinum clusters are plotted in Figure 1. The bond length and the binding energy of Ag₂, Au₂, Cu₂ and Pt₂, are listed in Table 1.

The Ag₂ dimer is calculated to have a bond length 2.56 Å. These values close to Zhao et al. [23], and are close to the experimental bond length value of 2.53 Å [24]. For the Au₂ dimer’s bond length (2.66 Å) is close to theoretical and the experimental studies [23,25,26]. For Cu₂ and Pt₂ the bond lengths are 2.17 Å, 2.55 Å, respectively, very close to other results experimental and theoretical results [27-31].

The variation of average Ag–Ag, Au–Au, Cu–Cu and Pt–Pt bond length of all the lowest energy structures as a function of cluster size is described in the Figure 2. For Ag₃, Au₃, Cu₃ and Pt₃, the lowest energy structures are linear chains with bond length 2.52 Å, 2.48 Å, 2.0 Å, 2.30 Å, respectively. The lowest energy structures of metal clusters with 4-5 atoms are found to adopt planar forms. Ag₄ is a planar rhombus with 2.63 Å bond length. For Au₄, Cu₄, and Pt₄ the bond lengths are 2.56 Å, 2.31 Å, 2.42 Å, respectively. Generally, for each metal, it is observed that the bond length value increases as the cluster size evolves from 3 to 10 atoms. The average bond length decreases for Ag₅, Ag₁₀, Au₅, Au₁₀ and Pt₅ in an exception of the general trend. The calculated average bond length of the gold, copper, silver and platinum clusters are in well agreement with the measured data [11,27,32].

Figure 2: Average bond lengths in Ag$_n$, Au$_n$, Cu$_n$, Pt$_n$ as a function of cluster size

**Binding energy**

The binding energy per atom was calculated for each metal cluster size $n$ as:

$$E_B = \frac{E_T - nE_{\text{atom}}}{n} \quad (1)$$

Where $E_T$ is the total electronic energy of a cluster and $E_{\text{atom}}$ is the total electronic energy for one isolated atom. The calculated binding energies of Ag$_2$, Au$_2$, Cu$_2$ and Pt$_2$ are 1.59 eV, 1.86 eV, 1.69 eV and 2.51 eV respectively. They approach the results of other theoretical [23,27,29] and experimental works [25,26,33,34] as shown in Figure 3. As seen in the plot, the binding energy per atom increases with the cluster size for each metal. This trend is due to the increase of the number of nearest-neighbours with increasing size, thus encouraging more average number of interactions per atom. The systems usually tend to gain stability; the larger clusters are thus more stabilized.

Figure 3: Binding energies per atom of Ag$_n$, Au$_n$, Cu$_n$ and Pt$_n$ as a function of cluster size

**Homo-lumo gap (HLG)**

The HOMO-LUMO gap is the energy between the highest occupied orbital (HOMO) and the lowest unoccupied orbital (LUMO) for the calculated lowest energy structures for each cluster. Transition from the atomic scale to bulk metallic behaviour is accompanied by a closure of the HOMO-LUMO gap and development of collective electronic excitations [35].

Figure 4 shows the size difference of the HOMO-LUMO gap. For silver, gold, copper and platinum clusters, there is clear odd-even oscillation. This oscillation can be understood by the electron pairing effect. The Ag, Au, Cu 5s electrons are delocalized around the whole cluster, while this observation is not recorded in Pt clusters. This is may be due to the fact that platinum clusters have unsaturated atomic orbitals. Larger HOMO-LUMO gap (HLG) is needed to excite the electrons valence band to conduction band.
Second differences total energies

The variation of second differences of clusters total energies $\Delta_2 E(n)$ as a function of clusters size is represented in Figure 5.

$$\Delta_2 E(n) = E(n + 1) + E(n - 1) - 2E(n) \quad (2)$$

As we have seen previously in HOMO-LUMO gap, we calculate $\Delta_2 E(n)$ for metal clusters. As shown in Figure 5. The second differences energies show dramatic odd-even oscillations. The even numbered Ag$_n$, Au$_n$, Cu$_n$ and Pt$_n$ clusters are relatively more stable than the neighbouring odd-sized and have also larger HOMO-LUMO gap values. Commonly the value of $\Delta_2 E(n)$ is known to represent the relative stability of a cluster of size n, with respect to its neighbours. Results related to silver, gold, copper and platinum are close [23,32,36]. The noticeable peaks at n=4, 6, and 8 indicate that these clusters should be more stable than their neighbours. It is also noticed that the cluster Pt$_3$ has more stable structure compared to other clusters of Ag, Au, Cu, of the same size. Pt$_3$, Pt$_5$, Pt$_7$ have larger second difference energy than their neighboring clusters. This means that they are the most stable, while Ag$_n$, Au$_n$, Cu$_n$, with (n=4, 6, 8) are the most stable clusters. It indicates that these clusters possess dramatically enhanced chemical stability and may be selected as the building block of novel nano-materials [37].

Vertical ionization potential (VIP)

Vertical ionization potential (VIP) is used to investigate the chemical stability of small clusters. The larger the VIP the less reactive or higher chemically stable the cluster.
In Figure 6, the size variation of ionization potential is plotted for the studied clusters. For linear chain trimer, \(\text{Au}_3\) and \(\text{Ag}_3\), our results are similar to experimental values (7.47 eV, 5.42 eV, 7.50 eV, 6.2 eV respectively) [38,39]. For \(\text{Pt}_3\), our result is slightly below experimental results (7.44 eV, 8.17 eV respectively) [40] whereas, for \(\text{Cu}_3\) the obtained result is close to that reported in other results (6.53 eV, 6.00 eV respectively) [27]. Computations a statement that VIP of small \(\text{Au}, \text{Cu}, \text{Ag}\) and \(\text{Pt}\) clusters generally decreases with cluster size.

![Figure 6: Ionization potential for silver, gold, copper and platinum clusters for different cluster size](image)

**Density of states**

The density of states gives important information about the ‘available’ charge (electron or fraction of it) for a given energy. For example, chemical activity of a cluster is proportional to the electron density near Fermi level [41]; the high the density in this region the more chemically active the cluster. In Figure 7, we present the variation of DOS for the studied clusters. As we can see, the highest DOS near Fermi level is present for \(\text{Cu}, \text{Au}\) and \(\text{Pt}\), while \(\text{Ag}\) clusters have little DOS in this region. Generally, the DOS peaks near Fermi level are located at energies in the range of 1.75 – 3 eV for \(\text{Ag}\) clusters, while for \(\text{Cu}\) and \(\text{Au}\) clusters the DOS peaks locate at energies ranging approximately from 0.25 to 1.75 eV. In contrast to this picture, the \(\text{Pt}\) clusters seem to have less shifting locations from Fermi level of 0.25-0.5 eV. From this analysis, we can predict that platinum and copper clusters can be the most chemically active with a ‘selective’ activation energy due to the energy distance variation from Fermi level with changing size which is important property for catalysis for example. In the other hand, these results are in good concordance with the ionization potential.

![Figure 7: Density of states for silver, gold, copper and platinum clusters for different cluster size](image)
CONCLUSION

In this paper, we performed DFT simulating annealing calculation of geometric and electronic structure of Cu$_n$, Ag$_n$, Au$_n$, Pt$_n$ clusters with $n$=3–10. Our results show that new structures are obtained for each cluster size comparatively for those reported in the literature. The second differences energies of cluster show that the lowest energy Ag$_n$, Au$_n$, Cu$_n$ with even numbers ($n$=4, 6, 8) are more stable than neighboring clusters. Pt$_n$ shows different behavior where the most stable is found for the odd numbers ($n$=3, 5, 9). The binding energies generally increase while the ionization potential generally decreases with the increase of clusters size and the HOMO-LUMO gap show clear odd-even oscillation. We found that the highest DOS near Fermi level is present for Au, Cu and Pt. A more investigation in the partial and projected DOS for these clusters may led to control the cluster electronic properties by adjusting its size.
